# NOISE ANALYSIS

## **1.1 INTRODUCTION**

Patching Associates Acoustical Engineering Ltd. was retained by Chinook Roads Partnership (Chinook) to assess the potential noise impact of the proposed Calgary Southeast Stoney Trail (SEST) roadway network from north of 17th Avenue SE to east of Macleod Trail South (Hwy 2A).

The purpose of this study is to determine the predicted noise levels generated by future traffic on the SEST for the existing (2011) first row residential developments adjacent to the project and if required, the height of barrier needed to maintain the Alberta Transportation (AT) target noise level of 65 dBA L<sub>eq</sub> (24 Hour). This study also determines the 45 dBA L<sub>eq</sub> (24 Hour) to 75 dBA L<sub>eq</sub> (24 Hour) noise contours for the proposed roadways.

Noise predictions for road traffic were developed using the Federal Highway Administration's Traffic Noise Model (FHWA TNM version 2.5) computer program based on the traffic volumes and detailed road designs provided by Chinook. Input data are included in Appendix E.

### **1.2 NOISE CRITERIA**

Sound is typically measured using the A-weighting scale and is commonly expressed as an Leq value. The A-weighted equivalent-continuous sound level is the noise descriptor used in the Alberta Transportation noise attenuation guidelines. This index is an energy average of the varying sound level over a specified period. The use of this index permits the description of a varying sound level environment as a single number. As the  $L_{eq}$  is an "average" level, the measured sound level may exceed the criterion level, provided the duration is limited. The L<sub>eq</sub> value considers both the sound level and the length of time that the sound level occurs. Appendix A provides a detailed explanation of the Leq as well as other units and descriptors used in noise analysis.

The AT Noise Attenuation Guidelines for Provincial Highways Under Provincial Jurisdiction within Cities and Urban Areas (adopted 2002) specifies that a basic noise abatement threshold level of 65 dBA Leq (24 Hours) may be received in a resident's yard at a location two metres inside the property line (away from the road right of way), at a height of 1.2 metres above the ground surface. Noise studies for AT are normally to be adjusted to the 10 year planning horizon.

For this study, PAAE was requested to examine the impact of traffic noise based on the contractual design traffic volume as per Schedule 18 from Alberta Transportation. The Schedule 18 design traffic volume takes into consideration an Average Annual Daily Traffic (AADT) of 95,000 vehicles per day (VPD) and the end of the Chinook concession period at the year 2043, whichever comes first. Both horizons examined are beyond the standard 10-year horizon stated in the Guideline.

A copy of the Noise Attenuation Guidelines for Provincial Highways under Provincial Jurisdiction within Cities and Urban Areas document is found in Appendix B.

# **1.3 MODEL INPUT**

Layouts for the SEST, crossing roads and the surrounding area were modeled using drawings received from Chinook using the Federal Highway Administration TNM 2.5 computer program.

Appendix C contains modeled coordinates for receivers and barriers. Appendix D contains modeled coordinates for roadways.

# 1.3.1 TRAFFIC DATA

Traffic volume projections for this study are based on AADT 95,000 VPD and 2043 year horizons for Stoney Trail and Deerfoot Trail. The following principles were considered:

- If the traffic volume of the mainline section at the 2030 year horizon reaches 95,000 VPD, the year 2030 traffic volume will be used for the noise prediction.
- If the 95,000 VPD traffic volume of the mainline section happens in some year between 2030 the noise prediction.
- If the traffic volume of the mainline section at the 2043 year horizon does not reach 95,000 VPD, the year 2043 traffic volume will be used for the noise prediction.

The following table summarizes the traffic volume projections for the noise prediction for the adjacent community areas.

and 2043, the traffic volume of the year that reaches the 95,000 VPD criteria will be used for

Impacted Study Area	Impacted Communities	Year Based Traffic volume projection
Stoney Tr - North of 17 <sup>th</sup> Avenue	Applewood Park	2043
Stoney Tr - From north of 22X to east of Deerfoot Trail	McKenzie Towne, Auburn Bay, Copperfield, Mahogany Marques Meadows	2043
Stoney Tr - From west of Deerfoot Trail to east of Sun Valley Blvd/Chaparral Blvd	Mountain Park, McKenzie, Cranston	2030
Stoney Tr - West of Sun Valley Blvd/Chaparral Blvd	Sundance, Chaparral	95,000 VPD at 2038
Deerfoot Tr - South of 22X to north of 196 <sup>th</sup> Avenue	Cranston, Auburn Bay	95,000 VPD at 2031
Stoney Tr - From south of 17 <sup>th</sup> Avenue to south of 114 <sup>th</sup> Avenue	No specific residential area considered	95,000 VPD (approximate year 2030), noise contour calculations only

Table 1 Traffic volume projections of SEST Stage 1 Design

Appendix E contains the projected traffic volumes and truck percentages provided in the Functional Planning Study by Earthtech ranging between 3% and 5% for the AM and PM peak periods on the SEST and between 2% and 11% on the crossing roads. Twenty-four hour traffic volumes were calculated based on the data provided indicating 20% of daily traffic occurring during the combined AM and PM peak hours. The SEST mainline and Deerfoot Trail (Hwy 2) were modeled carrying a 1:1 medium to heavy truck ratio. All the other crossing roads were modeled with a 2:1 medium to heavy truck ratio.

The predicted levels for the Stage 1 design were calculated based on the traffic volume projections at each of the Stoney Trail and Deerfoot Trail mainline segments using the assumption that the breakdown in vehicle traffic classifications remains the same.

The modeled speeds were based on the design speeds listed in Schedule 18. Vehicles were modeled traveling at 110 kph on SEST. Ramps were modeled ranging between 45 kph and 110 kph. Crossing roads with SEST were modeled at the speeds as follows:

Chaparral Blvd and Sun Valley Blvd, 70 kph Cranston Blvd and McKenzie Lake Blvd, 70 kph Deerfoot Trail South, 110 kph 196 Avenue SE (Cranston Road (W)/Seton Blvd (E)), 70 kph

52<sup>nd</sup> Street, 70 kph Highway 22X, east of the interchange 130 kph, west of the interchange 90 kph 88 Street SE, 90 kph 114 Avenue, 70 kph Glenmore Trail, 90 kph Peigan Trail, 80 kph 17 Avenue, 70 kph.

Environmental conditions used in the model were 20 degrees Celsius with 50% relative humidity.

## **1.4 FUTURE NOISE LEVEL PREDICTIONS**

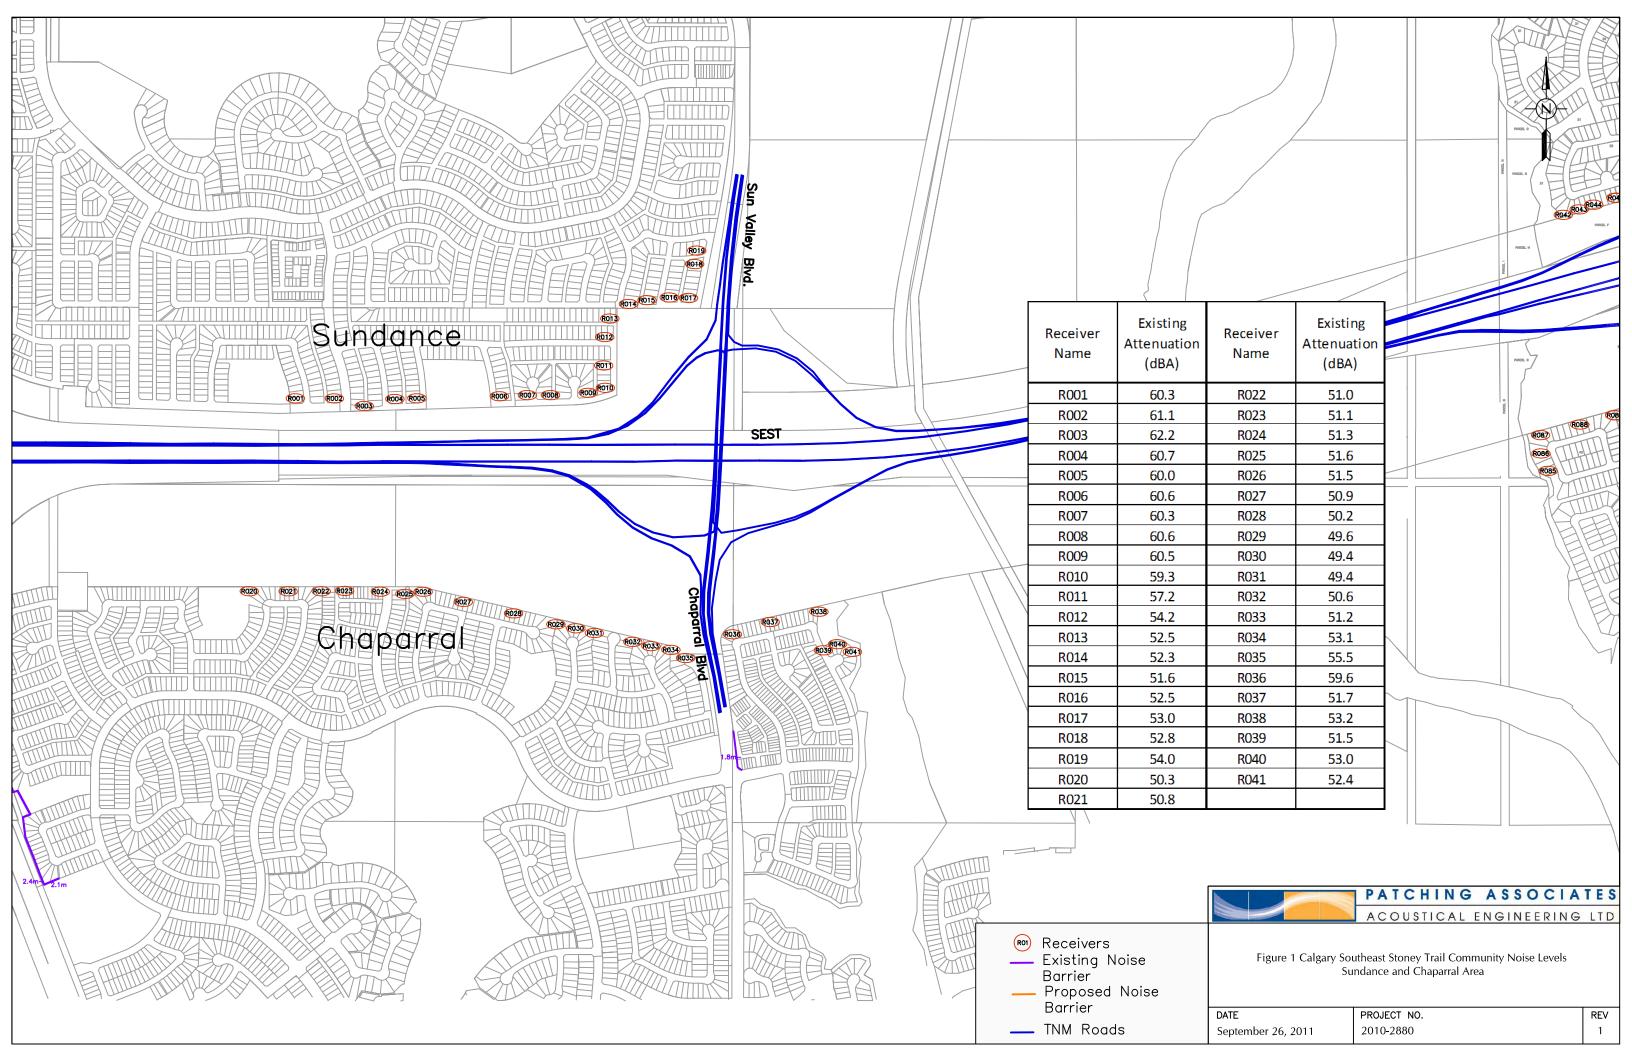

Based on the projected traffic volumes, grades of roads, speeds and land topography, predictions can be made for the noise levels that will be generated by the traffic at given receiver points and noise contours (isobels) for 65 dBA  $L_{eq}$  (24 Hours) can be plotted.

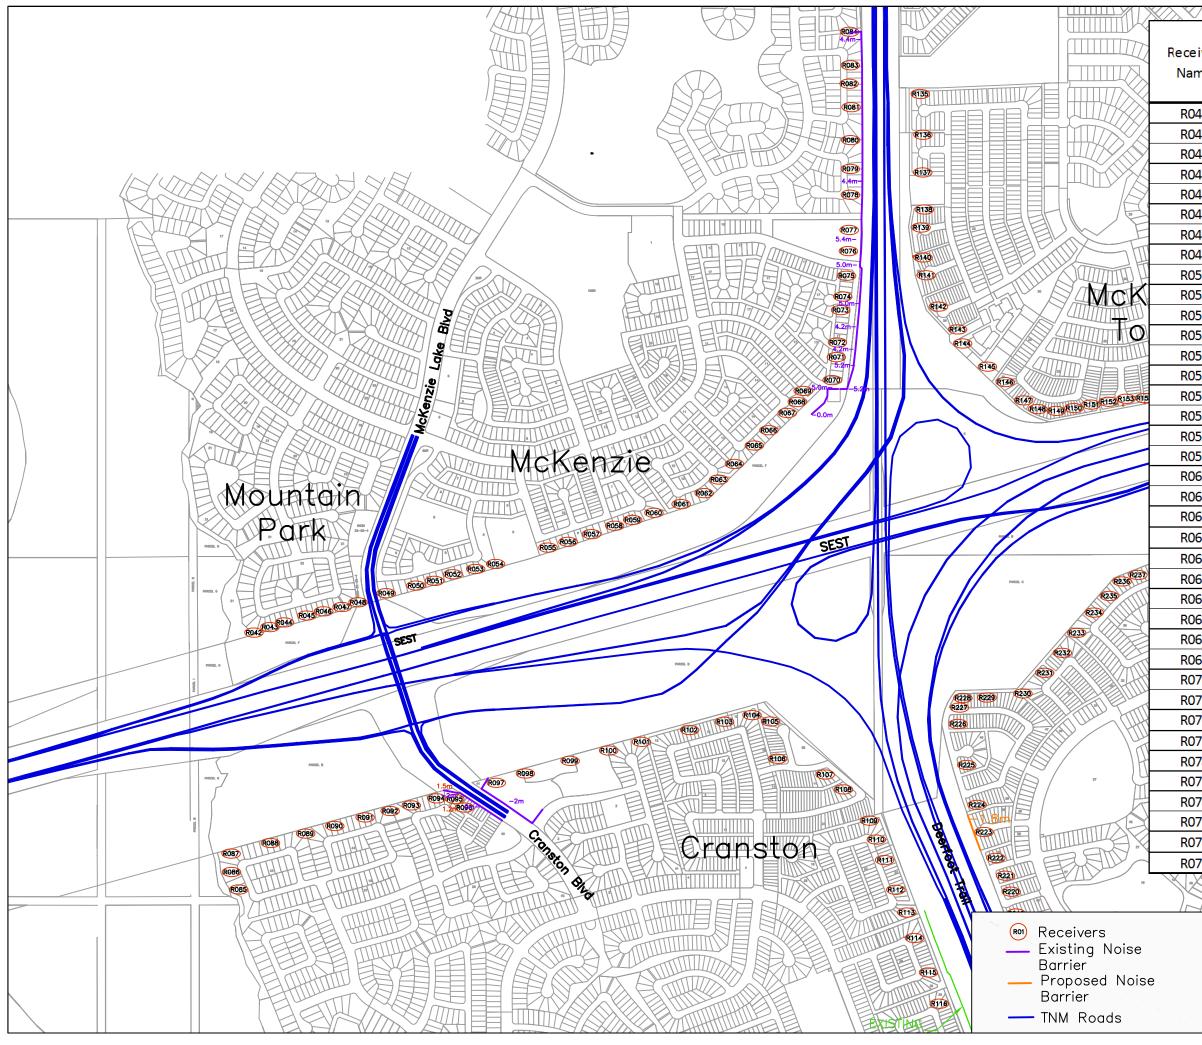

Figures 1 to 7 depict the modeled receivers along with corresponding predicted noise levels shown on Stage 1 plans.

The modeled results indicate that the 65 dBA L<sub>eq</sub> (24 Hours) noise target will not be exceeded for any receivers modeled for the existing (2011) communities of:

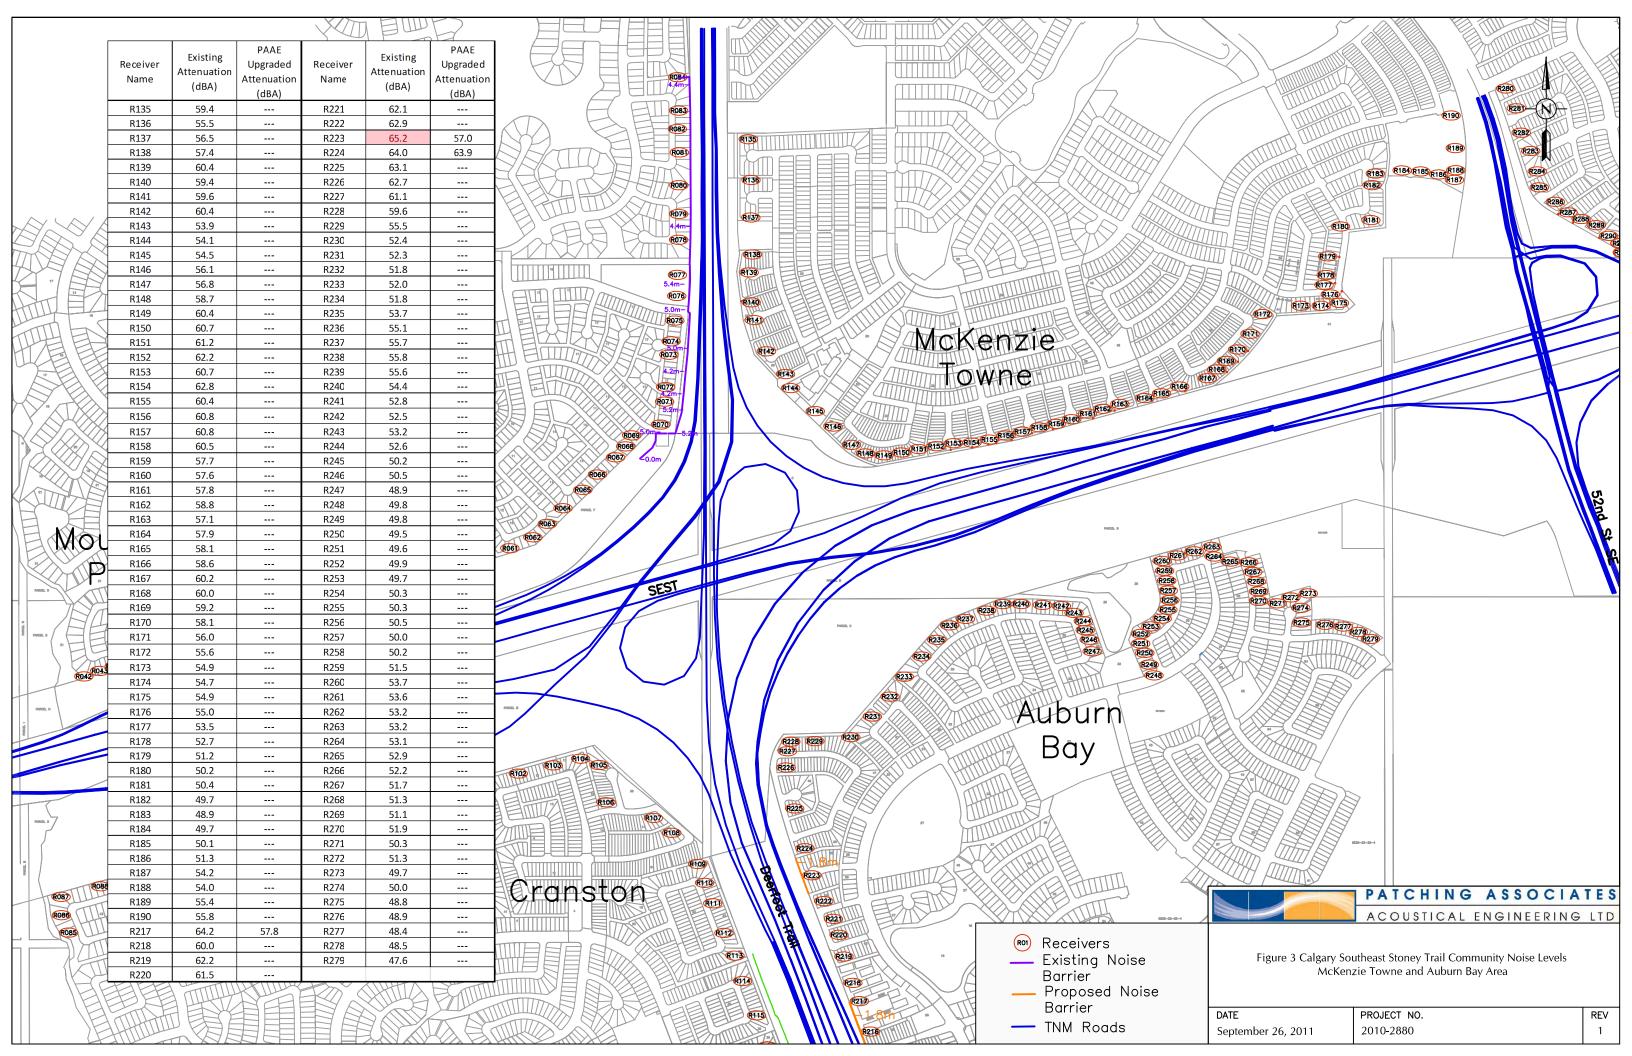

- Sundance and Chaparral	(Figure 1)
- Mountain Park, McKenzie	(Figure 2)
- McKenzie Towne	(Figure 3)
- Cranston	(Figure 2 and 4)
- Copperfield and Mahogany	(Figure 5)
- Copperfield and Marques Meadows	(Figure 6)
Areas that are predicted to exceed the target nois	se level include areas within the community of:

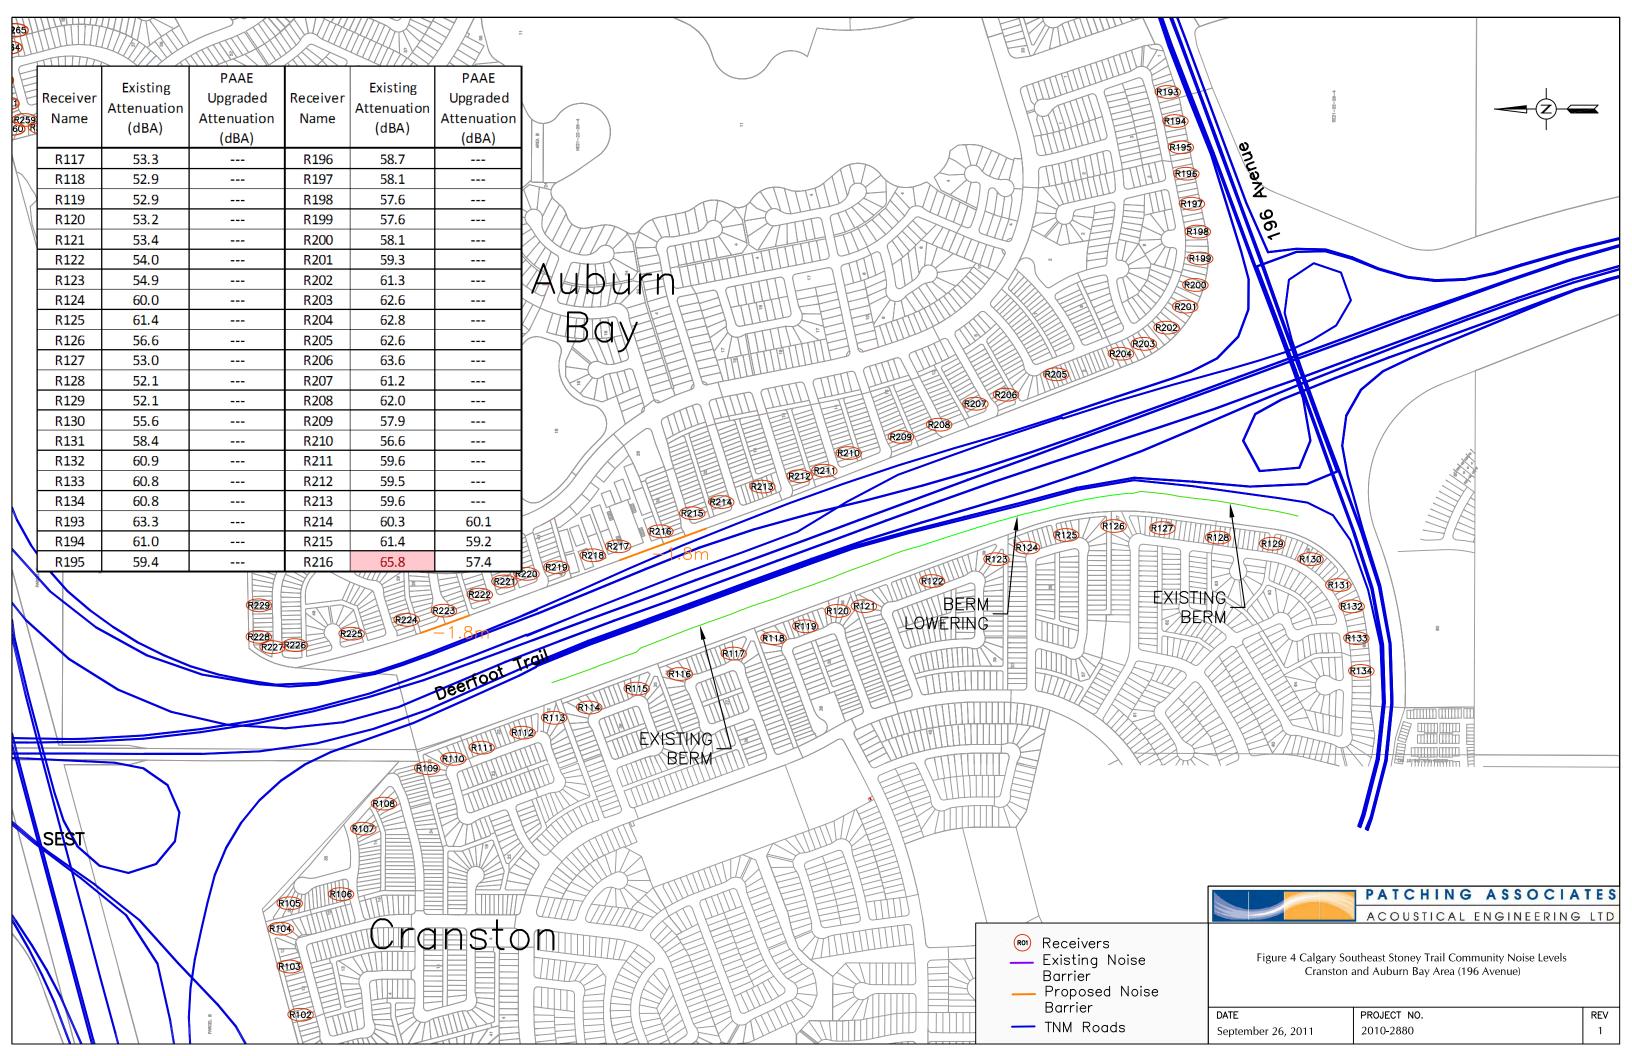

- (Figures 3 and 4) - Auburn Bay
- Applewood Park (Figure 7) -

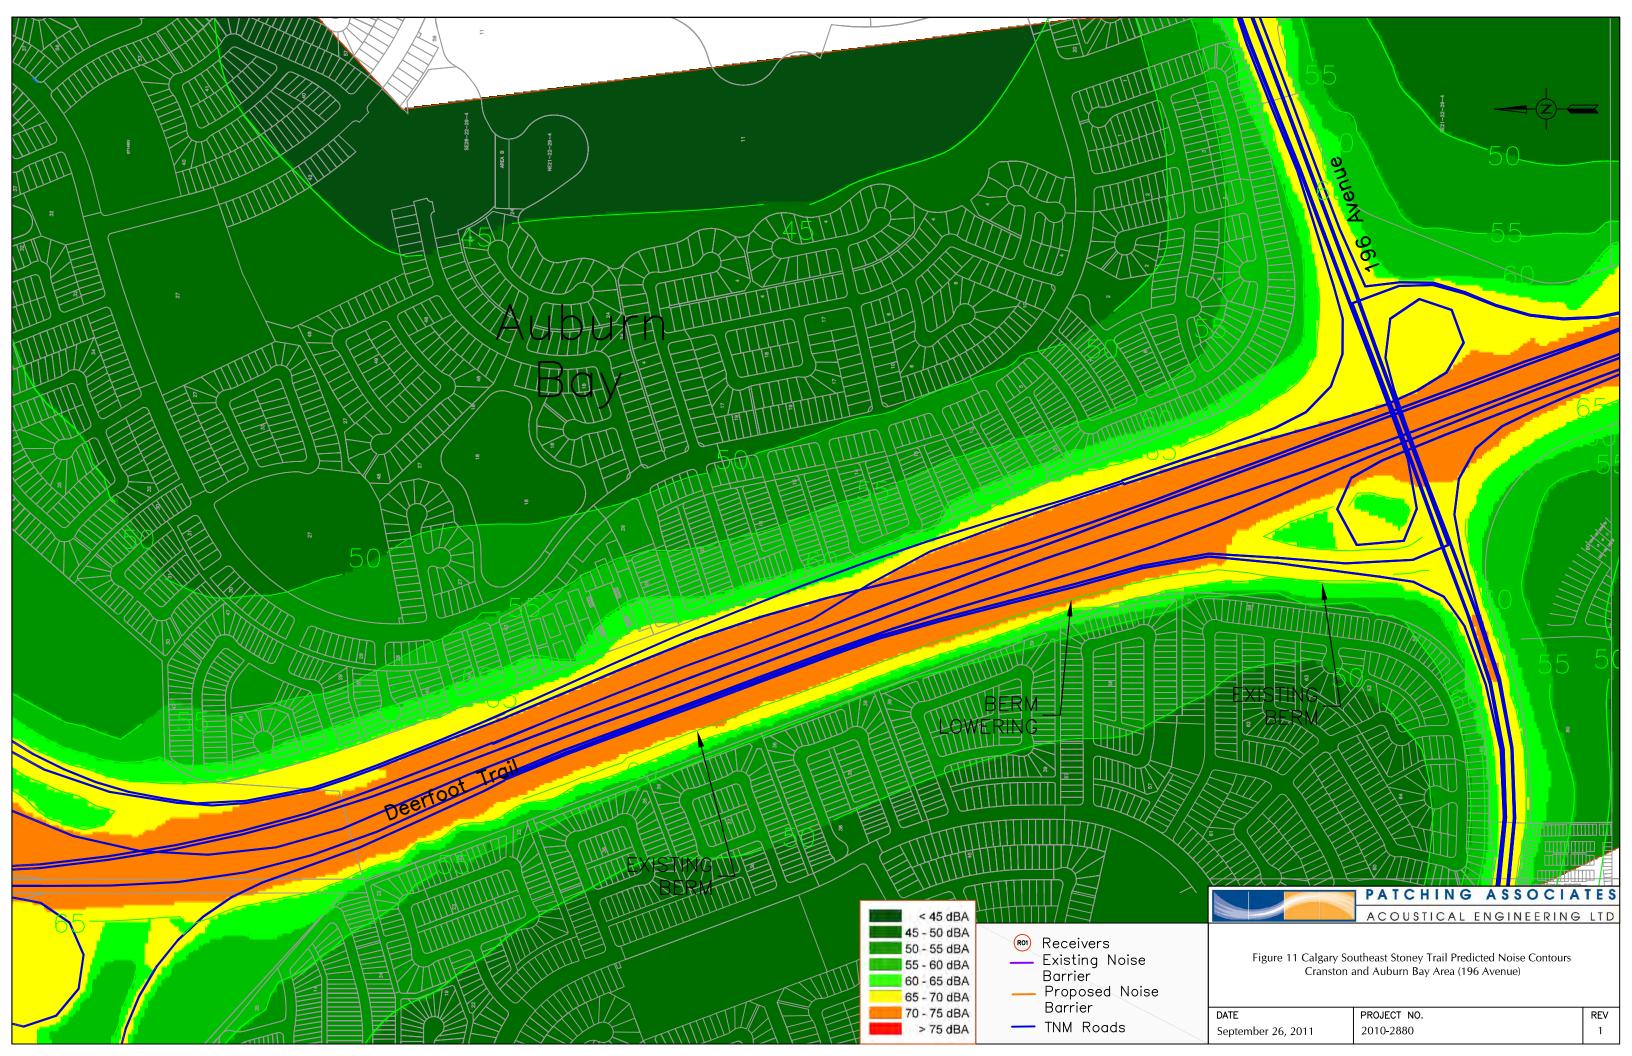

Figures 8 to 17 give a general depiction of the predicted noise levels adjacent to the roadways by plotting the locations of the 45 dBA to 75 dBA  $L_{eq}$  (24 Hour) noise contours at the mainline traffic designed volume. Each figure also shows the locations of the existing subdivisions and proposed roadways.

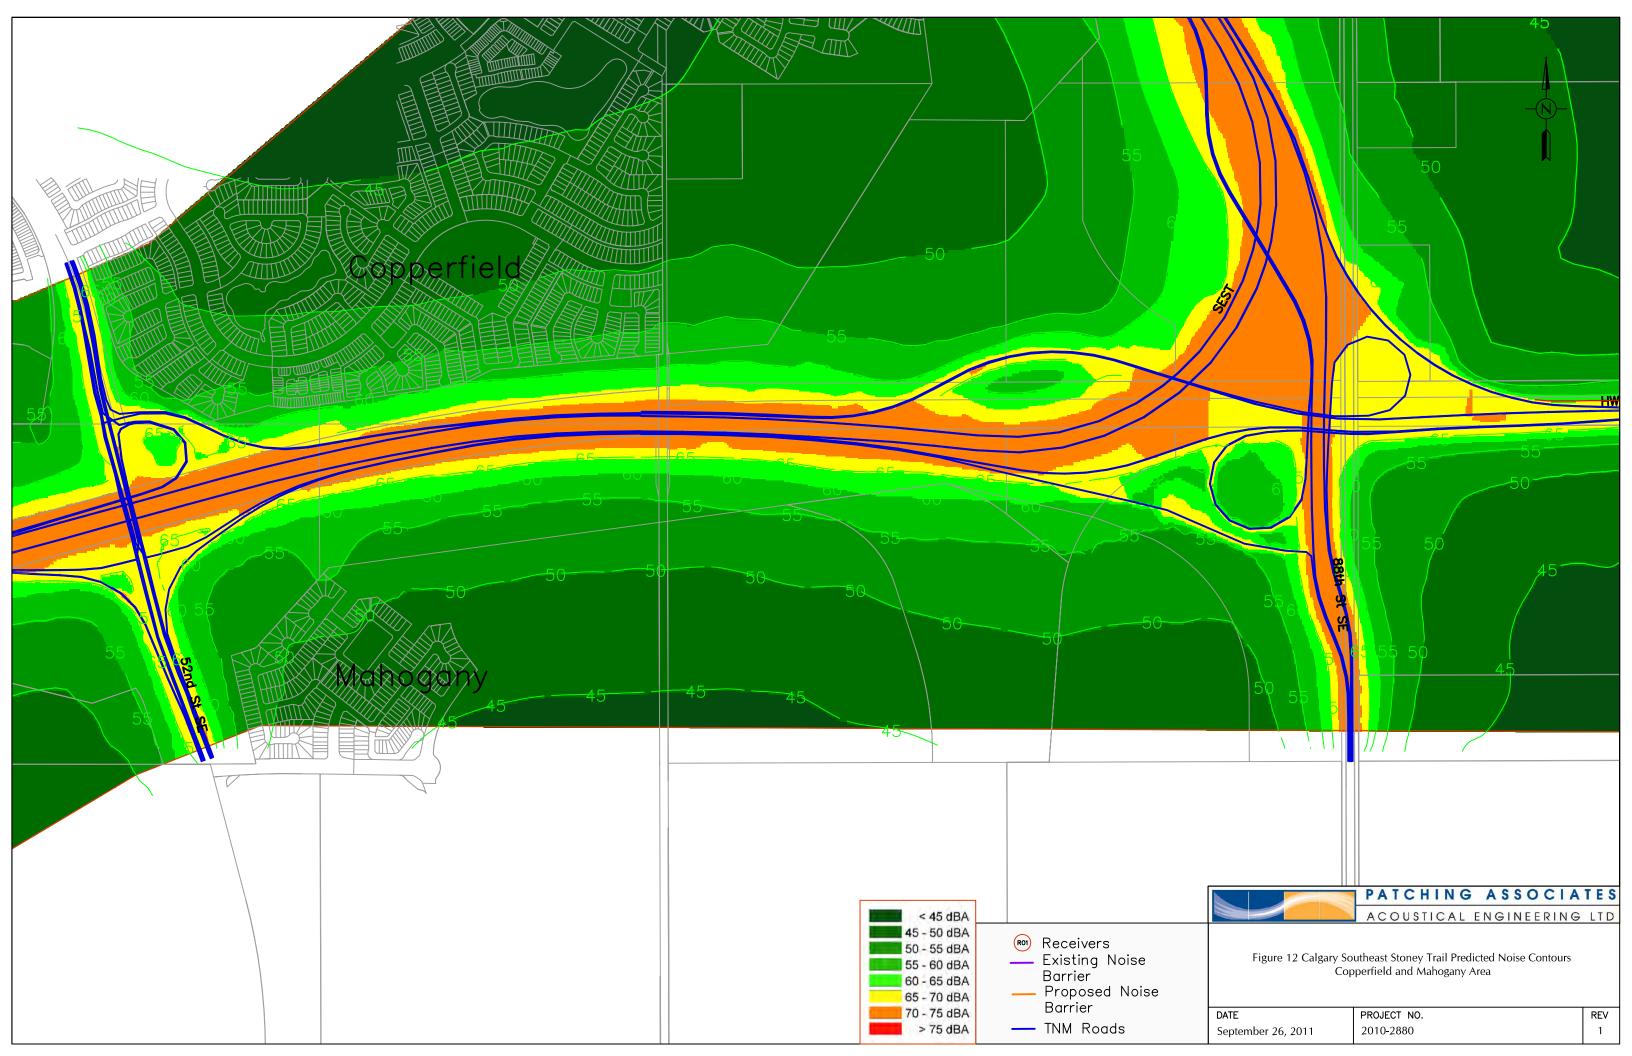

**Note:** The contours are based on interpolation for a range of grid points. The predictions for individual locations are based on the specific data for each site and as such, the individual predicted levels should be taken as more accurate in the event of any discrepancies.

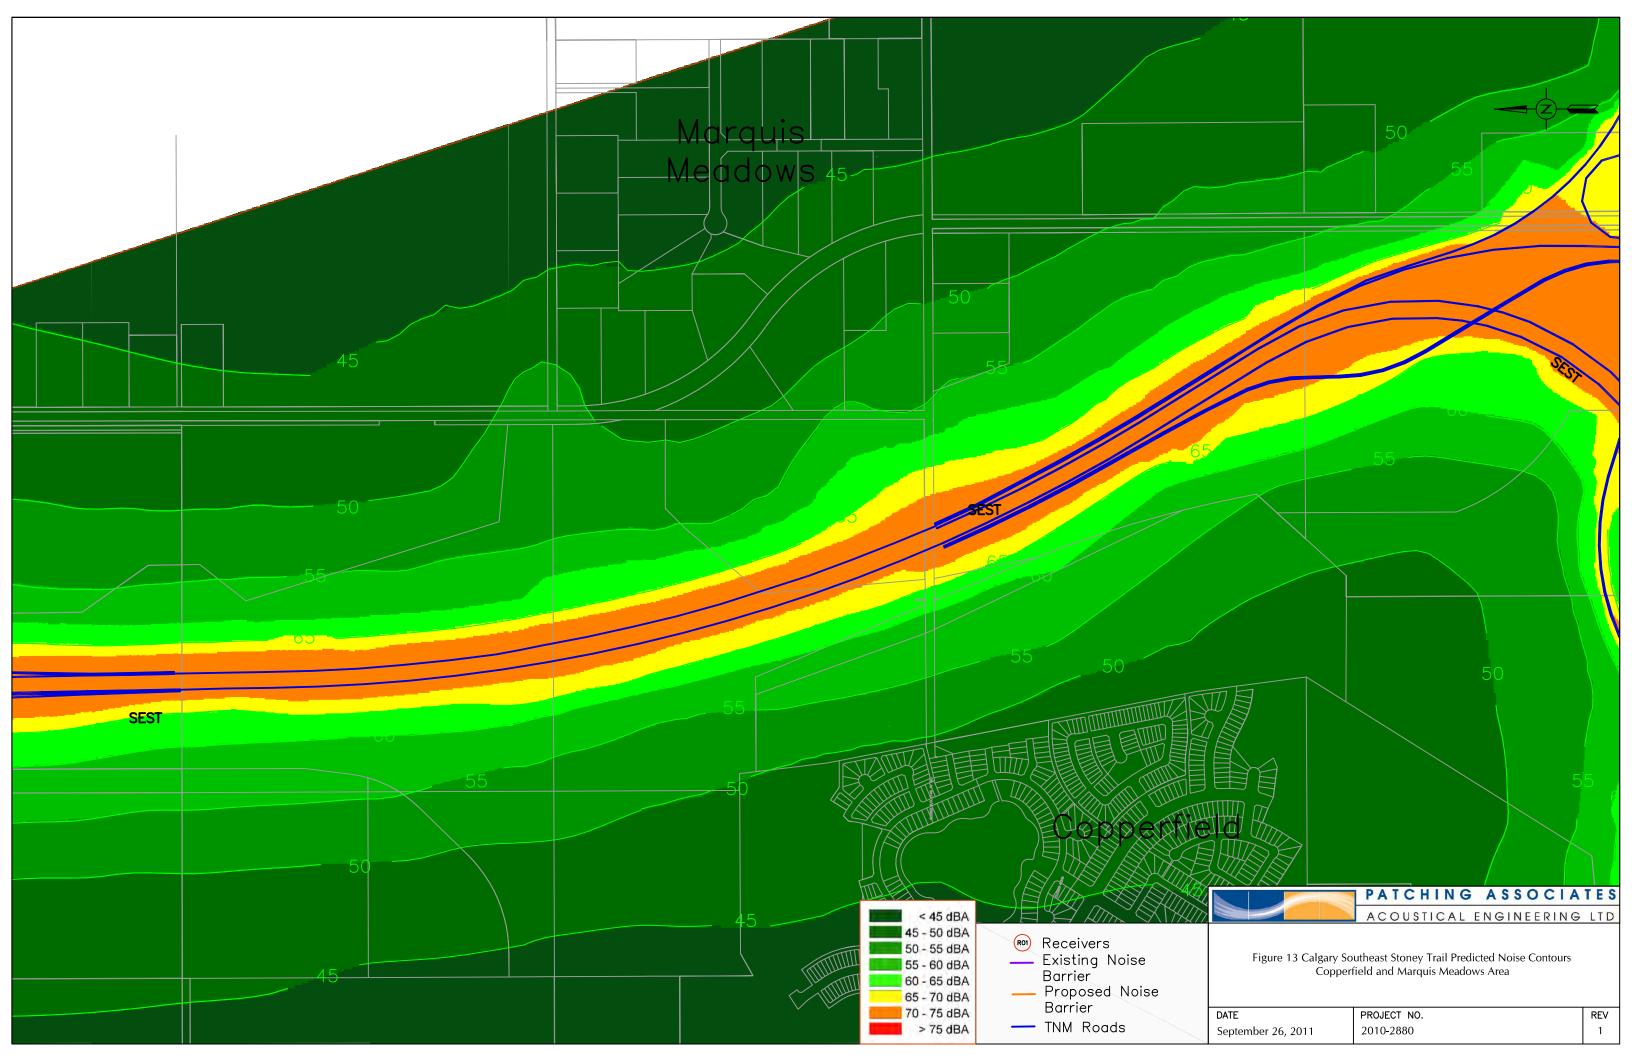

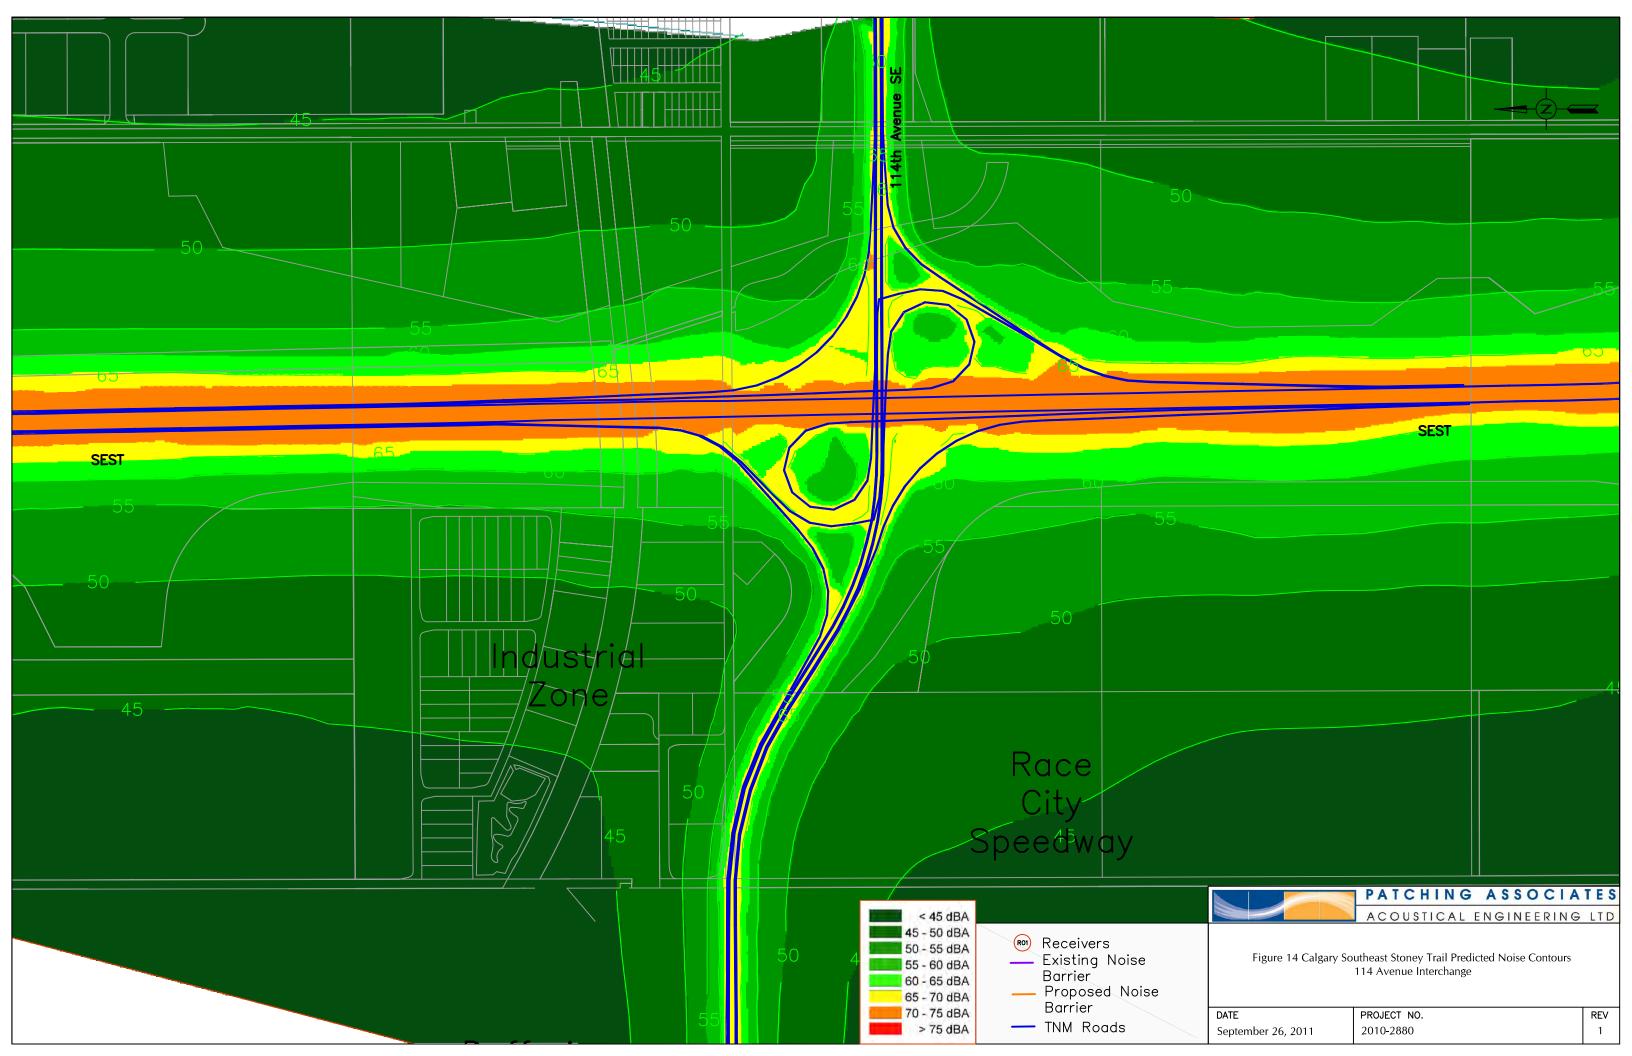

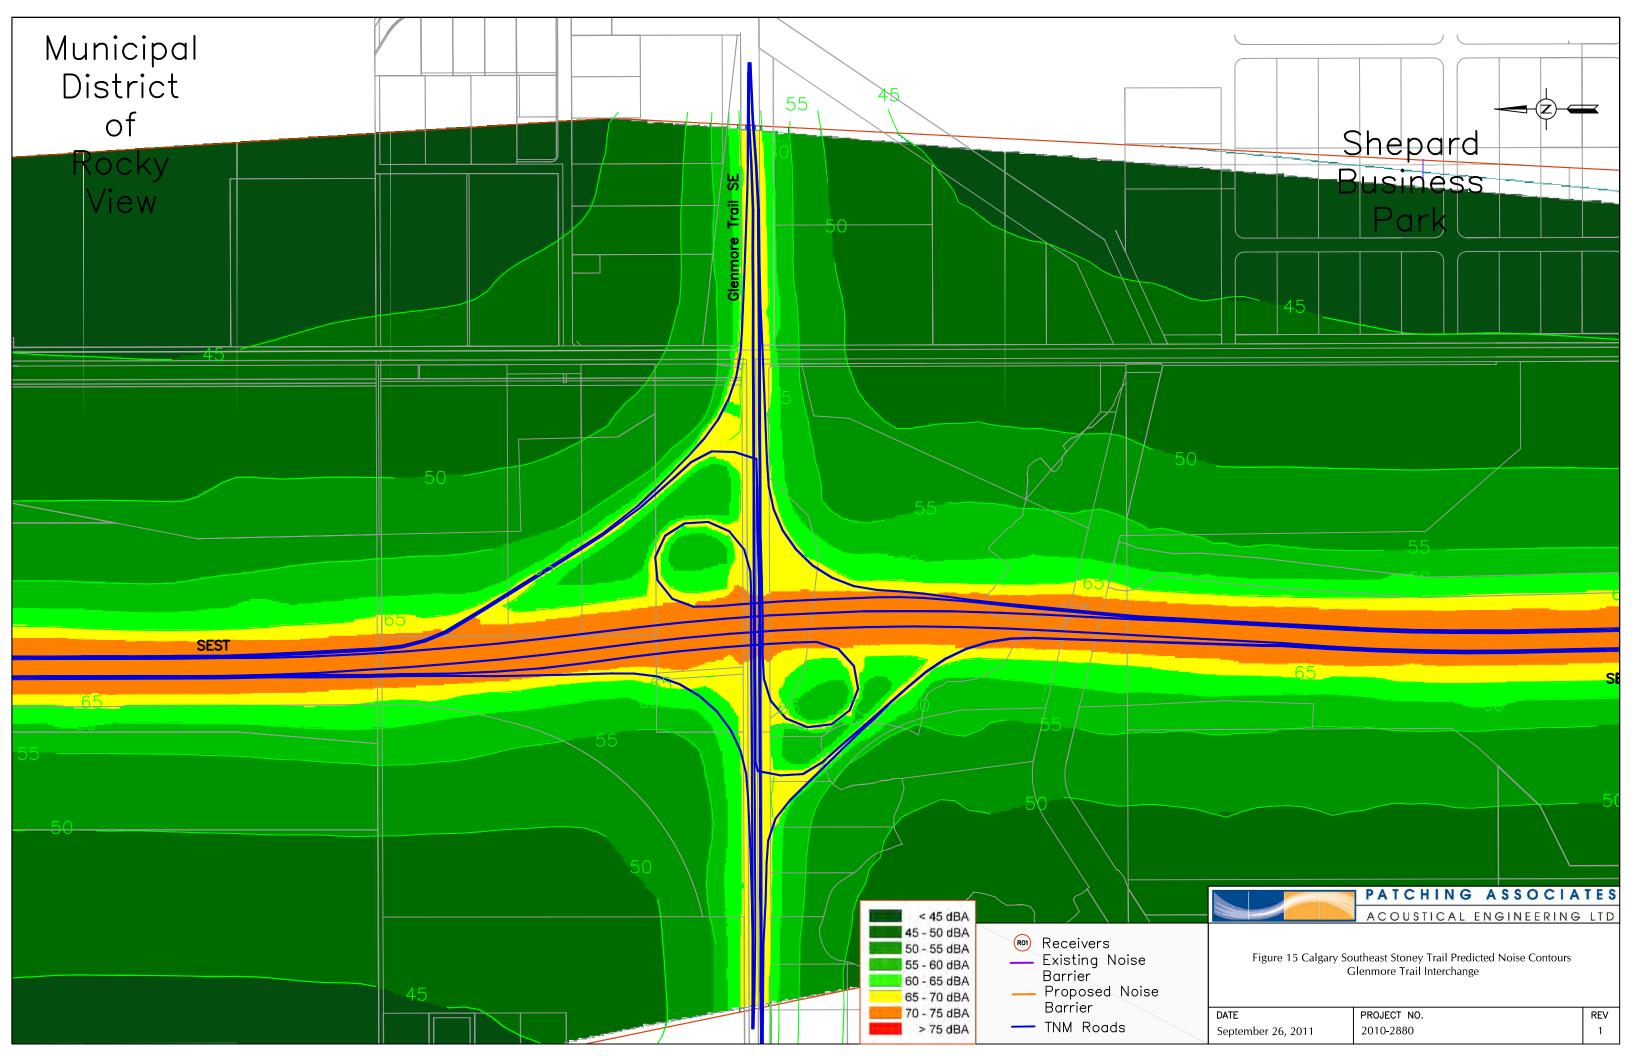

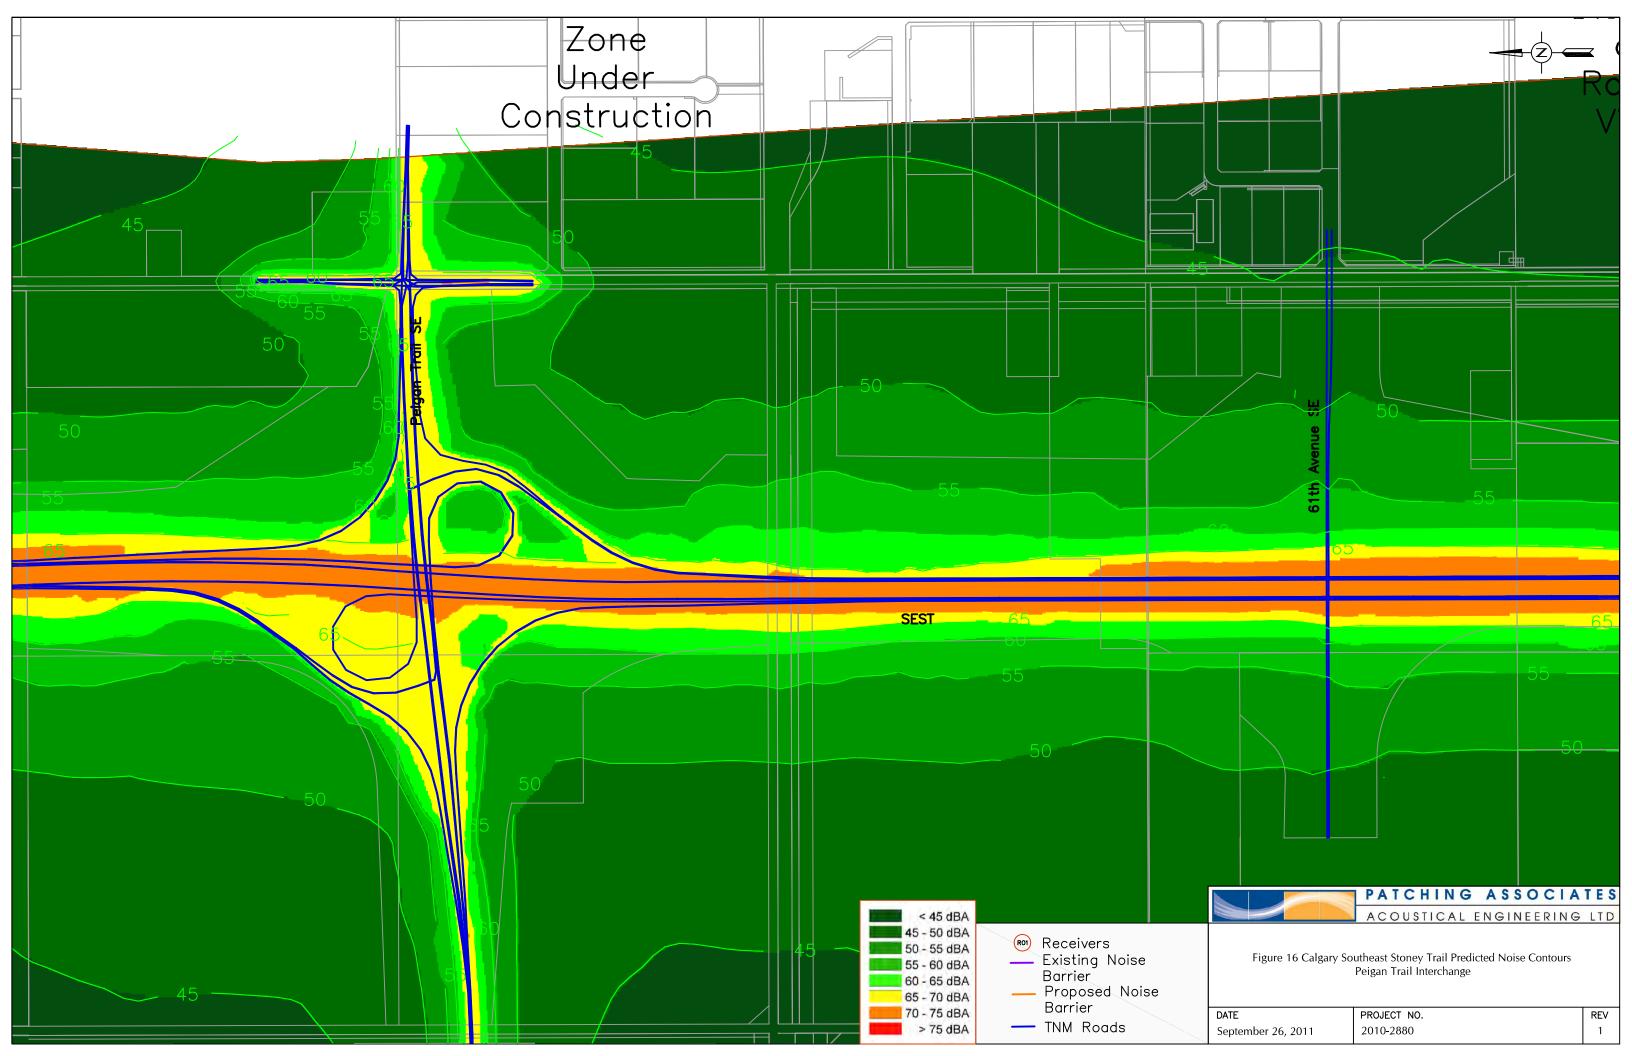

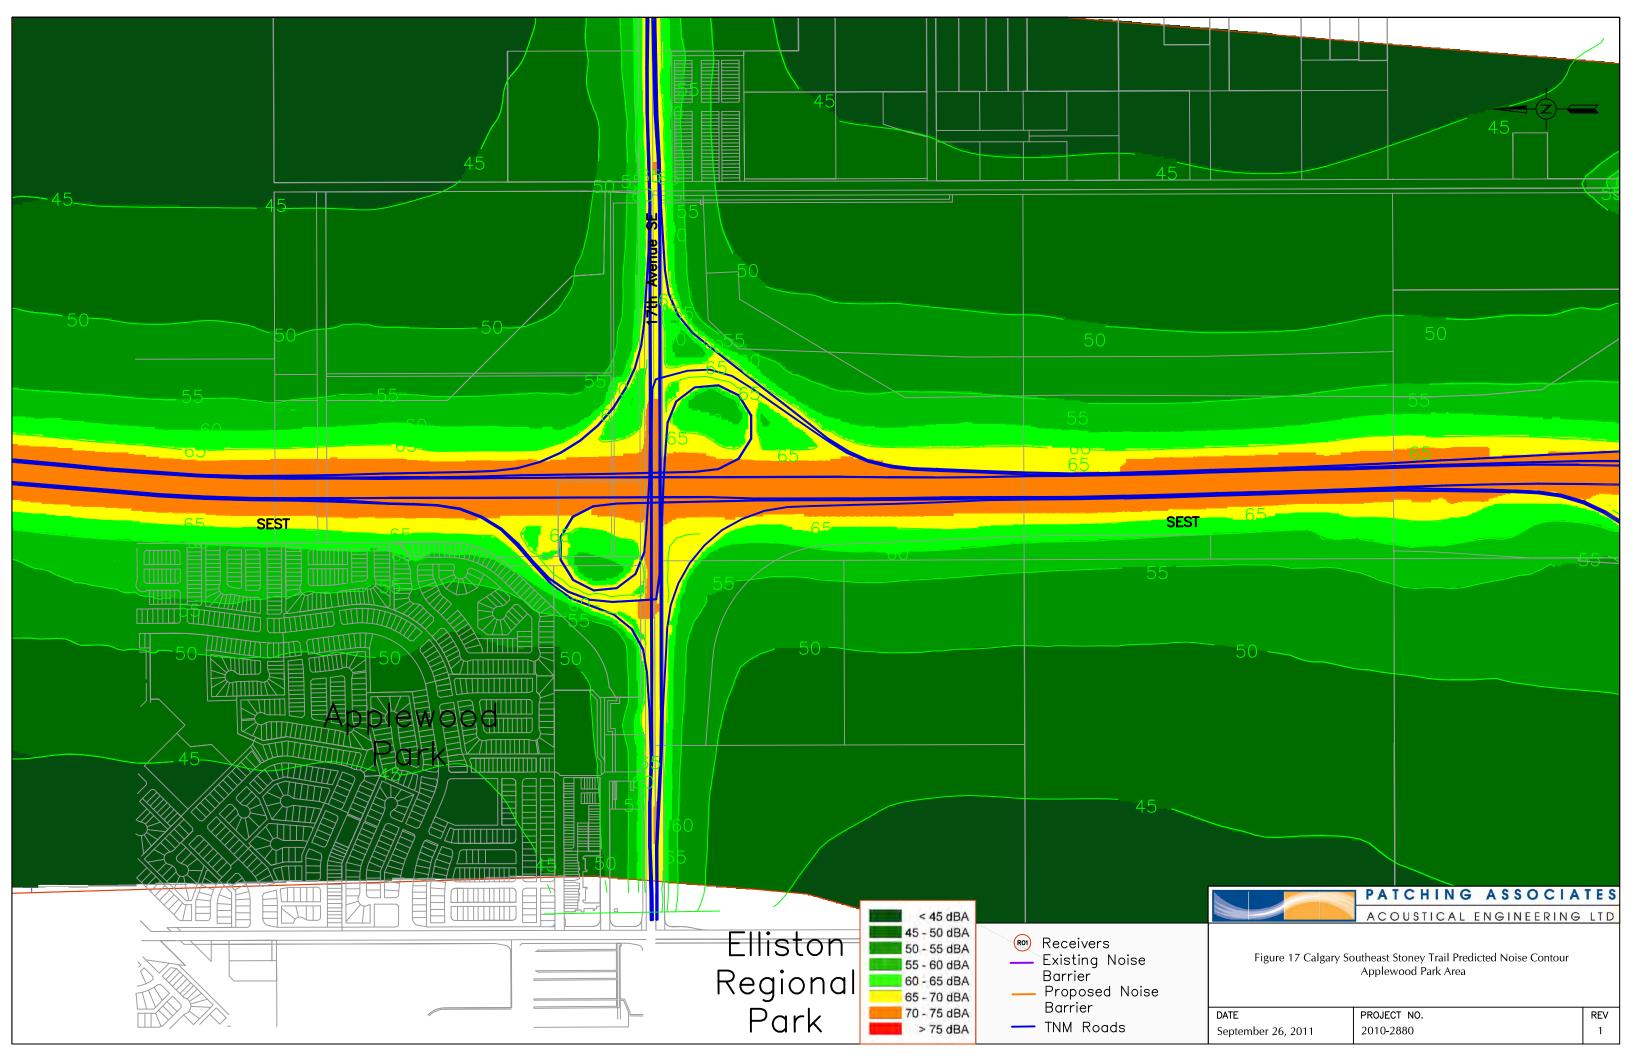

# 1.5 CONCLUSION

The analysis predicts that three short sections of noise wall 1.8 m in height are required on the east side of Deerfoot Trail and north of 17th Avenue. All other areas are assessed as receiving adequate benefit from existing screening or located with a separation distance great enough to the roadways to meet the AT target level. The communities considered in this analysis include:

-	Sundance	(Figure 1)
-	Chaparral	(Figure 1)
-	Mountain Park	(Figure 2)
-	McKenzie Lake	(Figure 2)
-	Cranston	(Figure 2 and 4)
-	McKenzie Towne	(Figure 3)
-	Auburn Bay	(Figure 3 and 4)
-	Copperfield	(Figure 5 and 6)
-	Mahogany	(Figure 5)
-	Marques Meadows	(Figure 6)
-	Applewood Park	(Figures 7)

**Explanation of Technical Details Regarding Sound Measurement & Analysis** 

#### **TECHNICAL DETAILS** 2

Sound is the phenomena of vibrations transmitted through air, or other medium such as water or a building structure. The range of pressure amplitudes, intensities, and frequencies of the sound energy is very wide, and many specialized fields have developed using different ranges of these variables, such as room acoustics and medical ultrasound.

Due to the wide range of intensities, which are perceived as sound, standard engineering units become inconvenient. Sound levels are commonly measured on a logarithmic scale, with the level (in decibels, or dB) being proportional to ten times the common logarithm of the sound energy or intensity. Normal human hearing covers a range of about twelve to fourteen orders of magnitude in energy, from the threshold of hearing to the threshold of pain. On the decibel scale, the threshold of hearing is set as zero, written as 0 dB, while the threshold of pain varies between 120 to 140 dB. The most usual measure of sound is the sound pressure level (SPL), with 0 dB SPL set at 2.0 X 10<sup>-5</sup> N/m<sup>2</sup> (also written 20  $\mu$ Pa), which corresponds to a sound intensity of 10<sup>-12</sup> Watts/m<sup>2</sup> (or 1 picoWatt/m<sup>2</sup>, written 1 pW/m<sup>2</sup>).

Normal human hearing spans a frequency range from about 20 Hertz (Hz, or cycles per second) to about 20,000 Hz (written 20 KHz). However, the sensitivity of human hearing is not the same at all frequencies. To accommodate the variation in sensitivity, various frequency-weighting scales have been developed. The most common is the A-weighting scale, which is based on the sensitivity of human hearing at moderate levels; this scale reflects the low sensitivity to sounds of very high or very low frequencies. Sound levels measured on the A-weighted scale are written in A-weighted decibels, commonly shown as dBA or dB(A).

When sound is measured using the A-weighting scale, the reading is often called the "Noise level", to confirm that human sensitivity and reactions are being addressed. A table of some common noise sources and their associated noise levels are shown in Table A1.

When the A-weighting scale is not used, the measurement is said to have a "linear" weighting, or to be unweighted, and may be called a "linear" level. As the linear reading is an accurate measurement of the physical (sound) pressure, the term "Sound Pressure Level", or SPL, is usually (but not universally) reserved for un-weighted measurements.

Noise is usually defined as "unwanted sound", which indicates that it is not just the physical sound that is important, but also the human reaction to the sound that leads to the perception of sound as noise. It implies a judgment of the quality or quantity of sound experienced. As a human reaction to sound is involved, noise levels are usually given in A-weighted decibels (dBA). An alternate definition of noise is "sound made by somebody else", which emphasizes that the ability to control the level of the sound alters the perception of noise.

The single number A-weighted level is often inadequate for engineering purposes, although it does supply a good estimate of people's reaction to a noise environment. As noise sources, control measures, and materials differ in the frequency dependence of their noise responses or production, sound is measured with a narrower frequency bandwidth; the specific methodology varies with the application. For most work, the acoustic frequency range is divided into frequency bands where the center frequency of each band is twice the frequency of the next lower band; these are called "Octave" bands, as their frequency relation is called an "Octave" in music, where the field of acoustics has its roots. For more detailed work, the octave bands, and certain standard octave and 1/3 octave bands have been specified by international agreements.

Source Or Environment	Noise
	Level
	(dBA)
High Pressure Steam Venting To Atmosphere (3m)	121
Steam Boiler (2m)	90-95
Drilling Rig (10m)	80-90
Pneumatic Drill (15m)	85
Pump Jack (10m)	68-72

Business Office	65
Conversational Speech (1m)	60
Light Auto Traffic (30m)	50
Living Room	40
Library	35
Soft Whisper (5m)	20-35

Where the noise at the receiver is steady, it is easy to assess the noise level. However, both the production of noise at the source and the transmission of noise can vary with time; most noise levels are not constant, either because of the motion of the noise source (as in traffic noise), because the noise source itself varies, or because the transmission of sound to the receiver location is not steady as over long distances. This is almost always the case for environmental noise studies. Several single number descriptors have been developed and are used to assess noise in these conditions.

The most common is the measurement of the "equivalent continuous" sound level, or Lea, which is the level of a hypothetical source of a constant level which would give the same total sound energy as is measured during the sampling period. This is the "energy" average noise level.

Table A1 Males Levels of E.

Typical sampling periods are one hour, nighttime (9 hours) or one day (24 hours); the sampling period used must be reported when using this unit.

The greatest value of the  $L_{eq}$  is that the contributions of different sources to the total noise level can be assessed, or in a case where a new noise source is to be added to an existing environment, the total noise level from new and old sources can be easily calculated. It is also sensitive to short term high noise levels.

Statistical noise levels are sometimes used to assess an unsteady noise environment. They indicate the levels that are exceeded a fixed percentage of the measurement time period measured. For example, the 10%-ile level, written  $L_{10}$ , is the levels exceeded 10% of the time; this level is a good measure of frequent noisy occurrences such as steady road traffic. The 90% level,  $L_{90}$ , is the level exceeded 90% of the time, and is the background level, or noise floor. A steady noise source will modify the background level, while an intermittent noise source such as road or rail traffic will affect the short-term levels only.

One disadvantage with the L<sub>eq</sub> measure, when used alone, is that nearby loud sources (e.g. dogs barking, or birds singing) can confuse the assessment of the situation when it is the noise from a distant source that is the concern. For this reason, the equivalent level and the statistical levels can be used together to better understand the noise environment. One such indication is the difference between the L<sub>eq</sub> and the L<sub>90</sub> levels. A large difference between the L<sub>eq</sub> and L<sub>90</sub>, greater than 10 dB, indicates the intrusion of short-term noise events on the general background level. A small difference, less than 5 dB, indicates a very steady noise environment. If the L<sub>eq</sub> value exceeds the L<sub>10</sub> value this indicates the presence of significant short-term loud events.

Some jurisdictions separate the daytime and nighttime, and calculate the  $L_{eq}$  for each time period. Typically, the daytime is defined as the hours between 7 AM (07:00) and 10 PM (22:00); the nighttime is defined as being between 22:00 and 07:00 the following morning. In some localities, the nighttime is defined as being from 11 PM (23:00) to 7 AM (07:00).

Other indexes exist for the evaluation of residents' response to the noise environment. One commonly used value is the Day-night level,  $L_{DN}$ . This index is similar to the  $L_{eq}$  measure taken over 24 hours, except that a penalty of 10 dBA is added to the noise levels at nighttime when calculating the  $L_{DN}$  value. This is to account for the greater sensitivity of people to noise which occurs during hours when most would like to sleep. For calculating this parameter according to the original definition from the US Environmental Protection Agency (EPA), "nighttime" is defined as being the time between the hours of 22:00 (10 PM) and 07:00 (7 AM).

Table A2 shows the adjustment factors used to approximate the equivalent  $L_{eq}$  (day),  $L_{eq}$  (night) and  $L_{DN}$  from the  $L_{eq}$  (24 Hours) based on the percentage of the total daily volume on the roadway at night. Previous studies on arterial roads and highways have shown that a typical range is between 10 and 15 percent of daily traffic occurring over the nighttime period.

**Note:** Table A2 assumes that vehicles are traveling at the same speed and the vehicle classification mix is unchanged throughout the day.

Percentage of	L <sub>eq</sub> (day)	L <sub>eq</sub> (night)	L <sub>DN</sub>

Appendix B

Noise Attenuation Guidelines for Provincial Highways Under Provincial Jurisdiction within Cities and Urban Areas

# NOISE ATTENUATION GUIDELINES FOR PROVINCIAL HIGHWAYS UNDER PROVINCIAL JURISDICTION WITHIN CITIES AND URBAN AREAS

#### **Definition:**

Noise is defined as the sounds generated by vehicles operating on the highway. It includes but is not limited to engine/exhaust sounds and road contact sounds.

#### **Guidelines:**

- For construction or improvements of highways through cities and other urban areas, Alberta Transportation will adopt a noise level of 65 dBA Leq<sub>24</sub> \* measured 1.2 metres above ground the level and 2 metres inside the property line (outside the highway right-of-way). The measurements should be adjusted to the 10 year planning horizon value, as a threshold to consider noise mitigation measures.
- The mitigation of noise issues could include constructing noise walls and/or berms. The decision to implement noise mitigation must consider whether mitigation is cost-effective, technically practical, broadly supported by the affected residents, and fits into overall provincial priorities.
- Any accepted noise mitigation measures consistent with this guideline will be the responsibility of Alberta Transportation. Where established local noise mitigation policies are more stringent than this guideline, the local policy may be considered on a shared responsibility basis.
- Alberta Transportation will be responsible for noise attenuation, in accordance with this guideline, in areas where Alberta Transportation is undertaking widening (by at lease one lane width) or major realignment of an existing road or constructing a new road adjacent to an existing residential development.
- In areas where a residential subdivision is constructed adjacent to an existing roadway, the development proponent will be responsible for noise attenuation consistent with these guidelines.
- In areas where a residential subdivision is constructed adjacent to a designated highway that has not been constructed, Alberta Transportation will request that the development proponent and approving authority address future noise concerns consistent with these guidelines.

\* Noise level expressed in decibels (dB) is taken to mean the A-weighted 24-hour equivalent sound level.
